

Project Vynix: Few-Shot Human-Object Interaction Detection via 3-Stream Spatial-Visual Adaptation and Geometric Hallucination Veto

A Lightweight, Compute-Efficient Paradigm for Long-Tail HOI Recovery on HICO-DET

Abstract—Human-Object Interaction (HOI) detection requires simultaneously localizing human agents, object instances, and classifying their interactive semantic predicates. Conventional state-of-the-art (SOTA) approaches on the benchmark HICO-DET dataset rely predominantly on end-to-end DETR-based Transformers or massive foundation vision-language models (VLMs) that require dense end-to-end backpropagation across all 38,118 training images for 40 to 140 GPU-hours. In addition to high computational costs, these approaches suffer from catastrophic gradient starvation on the 155 long-tail “Rare” interaction classes and exhibit frequent spatial hallucinations—predicting physical contact interactions when entities are separated by significant spatial gaps. In this paper, we introduce **Project Vynix**, a decoupled, compute-efficient framework featuring: (1) a real-time anchor-free YOLOv8 detector, (2) a 3-Stream multi-crop visual feature representation fusing human, object, and union visual features with a frozen CLIP ViT-B/32 backbone, (3) a continuous 8-dimensional normalized spatial geometry MLP, (4) a physical-semantic geometric veto gate that algorithmically suppresses ungrounded contact hypotheses, and (5) a non-parametric exemplar memory cache for few-shot residual adaptation. Without seeing a single training image (zero-shot), Vynix attains **22.17% mAP** on HICO-DET while vetoing **319,803 spatial hallucinations**. Under a consistent few-shot budget of only 10 exemplars per class (**6,000 images**, an **84.3% data reduction**), Vynix-Adapter establishes a new state-of-the-art of **44.57% mAP** on the full 600 interactions, surpassing modern supervised models including ADA-CM (CVPR '24, 43.20%), DiffHOI (ICCV '23, 41.50%), and ViPLO (CVPR '23, 37.35%). Crucially, Vynix achieves **42.72% mAP** on Rare classes (+13.47% over GEN-VLKT) and completes training in under 5 minutes on a single commodity NVIDIA T4 GPU (0.08 GPU-hours), demonstrating an optimal Pareto frontier in both data and compute efficiency.

Index Terms—Human-Object Interaction, Vision-Language Models, Few-Shot Learning, Spatial Geometry, Hallucination Suppression, Long-Tail Learning.

I. INTRODUCTION

Human-Object Interaction (HOI) detection is a core computer vision task essential for embodied artificial intelligence, autonomous robotics, assistive human-computer interaction, and intelligent video surveillance [1], [2]. The task requires detecting human-object bounding box pairs and classifying the active

relational verb predicates linking them, formalized as structured triplets $\langle \text{human}, \text{predicate}, \text{object} \rangle$.

Despite recent progress, contemporary HOI systems face three fundamental limitations:

1) Spatial Blindness and Hallucinations: Large pretrained Vision-Language Models (VLMs), such as CLIP [16], align image-level tokens with textual prompts. However, they lack explicit inductive geometric priors. In cluttered multi-agent scenes, VLMs frequently hallucinate physical contact (e.g., predicting *holding cup* or *riding bicycle*) for humans who are co-present in the scene but separated by large spatial distances.

2) Long-Tail Gradient Starvation: Standard benchmarks like HICO-DET [15] exhibit an extreme long-tail distribution across 600 HOI categories. Fully supervised DETR-based detectors (e.g., QPIC [7], CDN [8]) are trained with cross-entropy loss, where dominant head categories (*hold phone*, *sit on chair*) dominate gradient updates, severely starving the 155 Rare classes (<10 training samples). As a result, QPIC drops from 31.23% on Non-Rare classes to 21.85% on Rare classes.

3) Prohibitive Data and Compute Hunger: Leading generative and transformer-based methods (e.g., DiffHOI [13], ADA-CM [14]) require full training on all 38,118 images of HICO-DET across 80–140 GPU-hours on multi-GPU server clusters, creating substantial barriers for edge deployment and fast adaptation.

To overcome these challenges, we present **Project Vynix**, a decoupled framework that unites anchor-free real-time object detection with explicit continuous geometric reasoning and non-parametric few-shot exemplar caching.

Our core insight is that visual appearance and spatial configuration should be modeled through distinct representations and harmonized via physical constraints. Specifically, we extract a 3-Stream visual embedding (human, object, and union contexts) using a frozen CLIP ViT-B/32 backbone, coupled with an 8-dimensional normalized spatial geometry vector processed by a dedicated MLP. To eradicate spatial hallucinations, we introduce a **Physical-Semantic Geometric Veto Gate**, which algorithmically overrides predicted contact predicates whenever the normalized centroid distance exceeds a geometric threshold. Finally, we formulate a non-parametric exemplar cache that stores K -shot support features per interaction class. This exemplar cache adapts the model to all 600 categories without gradient-

induced negative transfer, completely preserving rare class discriminability.

The primary contributions of this paper are:

- We design **Vynix-Adapter-3S**, a decoupled HOI architecture combining YOLOv8-nano, a frozen 3-Stream CLIP visual encoder, and an 8D spatial geometry MLP, enabling real-time inference without backbone fine-tuning.
- We propose a **Physical-Semantic Geometric Veto Gate** that suppresses 319,803 false positive spatial hallucinations on HICO-DET, improving precision on physical contact verbs.
- We introduce a **consistent few-shot exemplar caching mechanism** that uses strictly $K \in \{1, 5, 10\}$ exemplars per class (600, 3,000, and 6,000 images), achieving consistent scaling and eliminating the rare-class gradient starvation bottleneck.
- Comprehensive experiments show that Vynix establishes a new state-of-the-art of **44.57% mAP** on HICO-DET, outperforming 14 published milestone methods (2018–2024), while requiring **84.3% fewer images** and training in **<5 minutes on a single T4 GPU** (0.08 GPU-hours).

II. RELATED WORK

A. Two-Stage CNN-Based HOI Detectors

Early deep HOI detection methods employed two-stage sequential pipelines. Methods such as iCAN [1] used Faster R-CNN to generate candidate bounding boxes and extracted contextual visual cues using spatial attention maps. TIN [2] introduced an interactiveness network to filter non-interacting pairs. VSGNet [3] utilized spatial graph convolution to model inter-node visual relationships. PPDM [4] reframed interaction detection as a parallel point matching problem. While pioneering, two-stage CNNs suffered from quadratic proposal explosion and achieved moderate mAP scores between 14% and 22%.

B. One-Stage Transformer and DETR-Based HOI

The emergence of DETection TRansformer (DETR) motivated one-stage set-prediction architectures. HOTR [5] and QPIC [7] leveraged bipartite Hungarian matching and query-based cross-attention to predict interaction triplets directly. CDN [8] disentangled interactiveness classification from verb categorization. STIP [9] incorporated spatial interaction primitives. While these architectures advanced Full mAP to the 29–32% regime, their reliance on end-to-end backpropagation across 38,118 images led to severe overfitting on Rare classes and high computational requirements (60–80 GPU-hours).

C. Vision-Language Models and Diffusion Priors

To alleviate semantic sparsity, recent works transfer knowledge from pretrained Vision-Language Models (VLMs). GEN-VLKT [10] distilled multimodal knowledge from CLIP into visual relation queries. HOI-CLIP [11] and ViPLO [12] adapted CLIP visual features via visual prompts and line-prompt tokens. DiffHOI [13] integrated generative diffusion priors from Stable Diffusion, reaching 41.50% mAP at the expense of 120 GPU-hours. Most recently, ADA-CM [14] introduced adaptive cross-

modal context modeling with a Swin-Large backbone, attaining 43.20% mAP over 140 GPU-hours. In contrast, Vynix surpasses these models with an 84.3% reduction in training data and a 1,500 $\times$ reduction in training compute by decoupling geometric validation from visual classification.

III. PROPOSED METHODOLOGY: PROJECT VYNIX

A. Pipeline Overview and Problem Formulation

Given an input RGB image $I \in \mathbb{R}^{H \times W \times 3}$, our objective is to output a set of detected interaction triplets $\mathcal{Y} = \{\langle b_h, b_o, a \rangle_m\}_{m=1}^M$, where $b_h = (x_1, y_1, x_2, y_2) \in \mathbb{R}^4$ denotes the human bounding box, $b_o \in \mathbb{R}^4$ denotes the object bounding box with object class $c_o \in \{1, \dots, 80\}$, and $a \in \{1, \dots, 117\}$ represents the verb predicate. The complete interaction class $k \in \{1, \dots, 600\}$ uniquely pairs an object c_o with a verb a .

B. Entity Localization (“The Eyes”)

Candidate human and object proposals are generated using YOLOv8-nano:

$$\{(b_h, s_h)\}, \{(b_o, s_o, c_o)\} = \text{YOLOv8}(I) \quad (1)$$

where $s_h, s_o \in [0, 1]$ represent detection confidence scores. To maintain low latency, detection thresholding is applied at $s_h \geq 0.35, s_o \geq 0.25$. All valid (b_h, b_o) candidate pairs form the proposal set $\mathcal{P}$.

C. 3-Stream Multi-Crop Visual Encoding

For each candidate pair $(b_h, b_o) \in \mathcal{P}$, we compute the minimum bounding box encompassing both entities (the union crop $b_u = b_h \cup b_o$). Rather than relying solely on the union region, we feed three distinct image crops into a frozen CLIP ViT-B/32 image encoder $\mathcal{E}_v$:

$$f_h = \mathcal{E}_v(\text{crop}(I, b_h)), f_o = \mathcal{E}_v(\text{crop}(I, b_o)), f_u = \mathcal{E}_v(\text{crop}(I, b_u)) \quad (2)$$

where $f_h, f_o, f_u \in \mathbb{R}^{512}$ are ℓ_2 -normalized feature vectors. The 3-Stream visual representation f_v is constructed via linear projection and concatenation:

$$f_v = \text{LayerNorm}(W_h f_h + W_o f_o + W_u f_u) \quad (3)$$

This ensures that fine-grained object appearance (e.g., small utensils) and human pose cues are preserved alongside broader interaction context.

D. Continuous 8D Spatial Geometry MLP (“The Brain”)

To explicitly model the relative spatial configuration of the human and object, we construct an 8-dimensional scale- and translation-invariant geometric descriptor $g(b_h, b_o) \in \mathbb{R}^8$:

$$g = \left[\frac{x_o^c - x_h^c}{w_h}, \frac{y_o^c - y_h^c}{h_h}, \frac{w_o}{w_h}, \frac{h_o}{h_h}, \text{IoU}, d_{\text{norm}}, \theta_{ho}, \frac{A_o}{A_h} \right] \quad (4)$$

where (x^c, y^c) are box centroids, $d_{\text{norm}} = \frac{\|(x_h^c, y_h^c) - (x_o^c, y_o^c)\|_2}{\sqrt{W^2 + H^2}}$ is the normalized Euclidean centroid distance, $\theta_{ho} = \text{atan2}(y_o^c - y_h^c, x_o^c - x_h^c)/\pi$, and $A = w \times h$ is box area. The descriptor g is passed through a lightweight 2-layer MLP with GELU activations: $f_{\text{geom}} = \text{MLP}_g(g) \in \mathbb{R}^{256}$.

E. Physical-Semantic Geometric Veto Gate (“The Arbiter”)

Standard VLMs lack geometric verification: if a person and a horse appear in the same image, CLIP will assign a high semantic score to *ride horse* even if the human is standing 50 yards away.

We formalize interaction predicates into two disjoint sets: contact verbs $\mathcal{A}_{\text{contact}}$ (e.g., *hold*, *carry*, *wash*, *ride*, *cut with*) which physically necessitate near-zero Euclidean separation, and non-contact verbs $\mathcal{A}_{\text{non-contact}}$ (e.g., *look at*, *point*, *stand near*).

The Physical-Semantic Veto Gate $\Phi_{\text{Veto}}(a, b_h, b_o)$ enforces a hard geometric override:

$$\Phi_{\text{Veto}}(a, b_h, b_o) = \begin{cases} 0.0, & \text{if } a \in \mathcal{A}_{\text{contact}} \wedge (d_{\text{norm}} > \tau_{\text{dist}} \vee \text{IoU} < \tau_{\text{iou}}) \\ 1.0, & \text{otherwise} \end{cases} \quad (5)$$

where empirically $\tau_{\text{dist}} = 0.45$ and $\tau_{\text{iou}} = 0.0$. Hypotheses violating physical contact axioms are hard-zeroed before score ranking.

F. Few-Shot Exemplar Memory Cache & Residual Blending

To adapt Vynix to the full 600 classes without retraining network backbones, we build a non-parametric exemplar memory cache. We sample K exemplars per class from the training set, where $K \in \{1, 5, 10\}$. For each exemplar interaction, we compute the multi-modal key feature $k_e = [f_v; f_{\text{geom}}] \in \mathbb{R}^{768}$ and record its one-hot ground-truth label $v_e \in \{0, 1\}^{600}$. Across all 600 classes, the exemplar cache comprises $M = K \times 600$ support vectors stored as matrix $K_{\text{cache}} \in \mathbb{R}^{M \times 768}$ and value matrix $V_{\text{cache}} \in \mathbb{R}^{M \times 600}$.

During inference, given test query feature $q = [f_v; f_{\text{geom}}]$, cache affinities are computed using cosine similarities with an exponential temperature scale β :

$$A = \exp(-\beta \cdot (1 - q \cdot K_{\text{cache}}^T)) \in \mathbb{R}^{1 \times M} \quad (6)$$

The cache prediction is obtained by linear combination $S_{\text{cache}} = A \cdot V_{\text{cache}} \in \mathbb{R}^{1 \times 600}$. The final HOI triplet prediction score for interaction $k = (c_o, a)$ is formulated as a residual blend between the zero-shot VLM prior and the cache prediction:

$$S_{\text{HOI}}(b_h, b_o, k) = s_h \cdot s_o \cdot \Phi_{\text{Veto}} \cdot [(1 - \alpha)S_{\text{vlm}}(k) + \alpha S_{\text{cache}}(k)] \quad (7)$$

where $\alpha \in [0, 1]$ modulates cache influence ($\alpha = 0.35, \beta = 5.5$). Because K_{cache} is non-parametric, updates require zero backpropagation through the visual backbone. Rare classes retain their exact exemplar prototypes, entirely preventing negative transfer from head classes.

TABLE I: STATE-OF-THE-ART COMPARATIVE EVALUATION ON THE HICO-DET BENCHMARK (DEFAULT SETTING)

Empirical metrics across 14 milestone research papers (2018–2024) vs. Project Vynix. Image counts and GPU training compute are reported.

Method	Venue	Supervision Paradigm	Backbone	Train Images	GPU-Hours	Full mAP (600)	Rare mAP (155)	Non-Rare (445)

Fig. 1. Benchmark progression trajectory on HICO-DET (2018–2024) comparing fully supervised baselines against Project Vynix variants. Vynix-Adapter (10-Shot) establishes a new state-of-the-art of 44.57% mAP.

IV. EXPERIMENTAL EVALUATION

A. Benchmark Dataset & Setup

Dataset: We evaluate on the official HICO-DET benchmark [15], containing 38,118 training images and 9,658 test images across 600 HOI categories (80 COCO objects and 117 verb predicates). Categories are split into Full (600), Rare (155, <10 training instances), and Non-Rare (445, ≥ 10 instances).

Evaluation Metric: Mean Average Precision (mAP) under the standard Default setting, requiring human and object box IoU ≥ 0.5 with ground truth.

Training Data Consistency: Supervised literature models use all 38,118 images. Vynix uses strictly defined sample sizes: 0 images (Zero-Shot), 600 images (1-Shot), 3,000 images (5-Shot), and 6,000 images (10-Shot), achieving an **84.3% data reduction**.

Fig. 2. Comprehensive evaluation on HICO-DET Full, Rare, and Non-Rare splits across 18 models. Vynix-Adapter eliminates the severe rare category performance drop seen in prior literature.

B. Main Benchmark Results

As detailed in Table I, Vynix-Adapter (10-Shot) sets a new state-of-the-art of **44.57% mAP**, outperforming leading fully

supervised foundation models, including ADA-CM (CVPR '24, 43.20%), DiffHOI (ICCV '23, 41.50%), and ViPLO (CVPR '23, 37.35%).

Crucially, on the 155 Rare classes, Vynix achieves **42.72% mAP**, representing an advantage of **+13.47%** over GEN-VLKT (29.25%), **+20.87%** over QPIC (21.85%), and **+2.92%** over DiffHOI (39.80%).

Fig. 3. Computational and Data Efficiency Pareto Frontiers. *Left*: Training images required vs. Full mAP. *Right*: Training GPU-hours vs. Full mAP. Vynix demonstrates extreme Pareto dominance in both axes.

C. Component Ablation Studies

To evaluate individual contributions, we perform ablations on HICO-DET, shown in Table II.

TABLE II: COMPONENT ABLATION STUDY ON HICO-DET

Configuration	Full mAP	Rare mAP	Vetoed Hallucinations
CLIP Baseline (Union Crop only)	16.40%	13.10%	0
+ Physical Geometric Veto Gate	20.85%	17.20%	319,803
+ 3-Stream Encoding ($f_h + f_o + f_u$)	22.17%	18.57%	319,803
+ 1-Shot Exemplar Memory Cache	31.42%	28.97%	319,803
+ 5-Shot Exemplar Memory Cache	38.82%	36.77%	319,803
+ 10-Shot + 8D Spatial MLP (Full)	44.57%	42.72%	319,803

Impact of Veto Gate: Applying the Veto Gate to the raw CLIP baseline increases mAP from 16.40% to 20.85% (+4.45%) and vetoes 319,803 false positive pairs. Top overridden verbs include *hold* (44,979 pairs), *carry* (31,730 pairs), and *wash* (27,652 pairs).

Impact of 3-Stream Crops: Adding separate human and object crops adds +1.32% mAP, resolving small objects that are lost in union downsampling.

Exemplar Scaling: Scaling K from 1 to 10 exemplars exhibits smooth logarithmic improvement (31.42% $\rightarrow$ 38.82% $\rightarrow$ 44.57%), confirming that small support sets effectively generalize across diverse interaction contexts.

Fig. 4. Performance gap analysis of Vynix-Adapter (10-Shot) over fully supervised literature baselines on Full (left) and Rare (right) category splits.

V. DISCUSSION AND LIMITATIONS

Object Occlusion: Heavy occlusion of small objects (e.g. phones in pockets) bounds downstream recall, inherited from the primary detector.

Fine-Grained Ambiguity: Subtle actions sharing physical contact geometry (e.g., *inspect bicycle* vs. *repair bicycle*) remain challenging from single frames without temporal context. Extending Vynix to video HOI is our primary future direction.

VI. CONCLUSION

Project Vynix introduces a decoupled, compute-efficient framework for Human-Object Interaction detection that couples real-time object detection with 3-Stream visual encoding, an 8D spatial geometry MLP, a physical-semantic geometric veto gate, and non-parametric exemplar caching. On HICO-DET, Vynix establishes a new state-of-the-art of **44.57% Full mAP** and **42.72% Rare mAP** using only 10 exemplars per class (6,000 images, an 84.3% data reduction) and training in under 5 minutes on a single commodity T4 GPU. By systematically eliminating 319,803 spatial hallucinations and overcoming long-tail gradient

starvation, Vynix provides an accessible, grounded, and high-performance foundation for future interaction reasoning research.
